

YangZhou 扬州

Package for Tuning (2nd Generation)

11/04/2023

Background

The purpose of this package is to provide a sophisticated framework for Greedy tuning. *The Criteria of Second Generation Tuning is to not have to train every specified discrete combination to get the optimum discrete result – or close to the optimum.*

The package takes in X and y data for train, validate and test as DataFrame, as well as a dictionary of {hyperparameters name -> string: hyperparameter values as a list}, and autogenerates all combinations of these hyperparameters to be tuned.

Algorithm Description

YangZhou begins by train-searching (i.e. searching the field by training the combination) all *Cruise Combinations* (mathematical combinations of all *cruise indices* from each dimension: *cruise indices* being i.e. [0, 4], [0, 5], [0, 3, 6] or [0, 4, 7] for dimensions containing 5, 6, 7 and 8 values respectively. The maximum gap between two indices is 5, minimum is 3).

Then, starting with the median combination (median index of each dimension) as the initial core, the *Guidance Algorithm* is activated, in which the ‘square’/‘cube’//higher dimension equivalent of $(3^d - 1)$ combinations’ surrounding each core (aka *Surrounding Coordinates*) is train-searched.

Then, *directions* are identified (see below for further explanation), and an algorithm gathers combinations which are determined to be *treatments* and *nulls* (see below for further explanation) for each *direction*. Then, a two sided welch statistical test (two sampled, assumed different variance) is performed, and for treatments where the directions where the treatment mean is larger than the null mean, and the test p-value ≤ 0.05 :

The first $n = \text{ceil}(d \times \ln(d))$ combination(s) matching the direction (see below for further explanation) will be added as new cores to be iteratively train-searched out. (In the case if the ‘direction combination’ is out of bounds, then the largest scoring combination will replace the ‘direction combination’ as the new core)

The *Guidance Algorithm* is then repeated for each of the new cores. When no new cores need to be tested, the maximum scoring combination will get a surrounding 3^d train-search (all surrounding $(3^d - 1)$ combinations), and if a new maximum scoring combination is found, then it will also get a surrounding $(3^d - 1)$ combinations search until no new maximum scoring combination can be found. The *Guidance Algorithm* is then terminated.

The *Cruise algorithm* is then subsequently activated, in which each of the cruise combinations scores will be compared to the current best scoring combination and its surrounding 3^d combination block (including itself). If a cruise combination's score is higher than the

$$\text{warning threshold} = \text{mean}(\text{best surrounding block}) - qt(0.95) * \frac{sd}{\sqrt{3^d}}$$

then the *Guidance Algorithm* will be restarted on that Cruise combination.

The *Cruise Algorithm* terminates once all cruise combinations have been compared to the warning threshold (which could change as the *Cruise Algorithm* goes on)

Once the *Cruise Algorithm* ends, the *Guidance Algorithm* gets activated one more time starting at the current maximum scoring combination, and the whole *YangZhou Algorithm* ends when this call of *Guidance Algorithm* is finished.

Note: although scores of certain combinations will undoubtedly be called upon multiple times, they can be stored and thus the expensive basic operation of train-searching a combination will only ever need to be completed once for each combination.

Further explanations of concepts:

Directions:

Horizontal directions will consist of all combinations that start at $[0, 0]$ and pick one and only one dimension to either be $+1$ or -1

i.e. for 2d, horizontal directions will consist: $[-1, 0]$, $[1, 0]$, $[0, -1]$, $[0, 1]$

Diagonal directions will consist of all combinations of all directions being either $\{-1, 1\}$

i.e. for 2d, diagonal directions will consist: $[-1, -1]$, $[-1, 1]$, $[1, -1]$, $[1, 1]$

Horizontal treatment and nulls:

Horizontal treatments will consist of all surrounding combinations with the same indices on the *non 0-valued dimensions* in the *direction* as its *combination matching the direction*.

Horizontal nulls will consist of all surrounding combinations with the same indices on the *non 0-valued dimensions* in the *direction* as its *core*.

i.e. for this example, core is $[3, 3]$; direction is $[-1, 0]$; combination matching the direction is $[2, 3]$; non 0-valued dimension is the 1st dimension (i); horizontal treatments are $[2, 2]$, $[2, 3]$, $[2, 4]$; horizontal nulls are $[3, 2]$, $[3, 3]$, $[3, 4]$

	i	0	1	2	3	4	5	6
j	0							
1								
2				✓	✓	✓		
3				✓	✓	✓		
4				✓	✓	✓		
5								
6								

Note: A more intuitive name would be 'Parallel', but 'horizontal' is what has been used in the code.

Diagonal treatments and nulls:

Diagonal treatments will consist of all surrounding combinations that has *relative direction vector* to the core in which every dimension is either exactly the same as that in *direction*, or is set to 0, excluding for the *core* which has *relative direction vector* $[0, 0]$.

Diagonal nulls will consist of the core and all surrounding combinations that has *relative direction vector* to the core which is orthogonal (dot product = 0) to *direction*. This of course includes the *core* which has *relative direction vector* $[0, 0]$

i.e. for this example, core is $[3, 3]$; direction is $[-1, -1]$; combination matching the direction is $[2, 2]$; diagonal treatments are $[2, 2]$, $[2, 3]$, $[3, 2]$; diagonal nulls are $[2, 4]$, $[3, 3]$, $[4, 2]$

-All these concepts generalise well to higher dimensions

Algorithm Assumptions

1. The scores observed from the same {data, model, hyperparameter combination, split size} belongs to the same underlying population which are normally distributed around a theoretical value.

i.e. Accuracies of SVM on a fixed set of hyperparameters with 80-20 split size on the same set of data (but with random holdouts of 80% training data) is considered to be sampled from the same population (and thereby same distribution)

2. Numerical values/ordinal values of hyperparameters should have trends (may be nonlinear so can't say they are correlated) with model scores. Different hyperparameters may also have interaction.

=> the movement of scores along the space should generally be smooth (*i.e. there won't be one combination with very high score when all close-by combinations have extremely low score*). Not exactly like a continuous plane/higher-dimensional-structure but the expectation is it behaves like a continuous plane/higher-dimensional-structure

Class

<u>Class</u>	<u>Purpose</u>
YangZhou	Object that performs greedy tuning

Methods:

<u>Methods</u>	<u>Purpose</u>
<i>YangZhou()</i>	Initialisation
<code>read_in_data(train_x, train_y, val_x, val_y, test_x, test_y)</code>	<p>Read in Train Test Split data</p> <p>Parameters:</p> <p>train_x – pd.DataFrame train_y - pd.Series val_x - pd.DataFrame val_y - pd.Series test_x - pd.DataFrame test_y – pd.Series</p>
<code>read_in_model(model, type)</code>	<p>Read in the underlying model class that we want to tune to get optimal parameters for</p> <p>Parameters:</p> <p>model – any model class that allows .fit() and .predict()</p> <p>type – str – either “Classification” or “Regression”</p>
<code>set_hyperparameters(parameter_choices)</code>	<p>Read in the different values of each hyperparameters we want to try. Function will automatically generate each combination</p> <p>Parameters:</p> <p>parameter_choices – dict of str:list – str is hyperparameter</p>

	name (strictly as defined in model class), and list is sorted values of hyperparameter which we want to try out.
<code>set_non_tuneable_hyperparameters(non_tuneable_hyperparameter_choice)</code>	<p>Reads in values for non-tuneable hyperparameters (i.e. doesn't need to clog up the tuning output csv)</p> <p>Parameters: non_tuneable_hyperparameter_choices – dict of str:int</p>
<code>set_features(ningxiang_output)</code>	<p>Reads in feature combinations for tuning</p> <p>Parameters: ningxiang_output – dict of tuple:float</p>
<code>set_tuning_result_saving_address(address)</code>	<p>Set saving address for tuning output csv</p> <p>Parameters: Address – str - does not need to include '.csv'</p>
<code>tune(key_stats_only = False)</code>	<p>Begin tuning process</p> <p>If key_stats_only = True then don't calculate non important stats</p> <p>Parameters: key_stats_only – bool</p>
<code>tune_parallel(part, splits, key_stats_only = False)</code>	Begin tuning process, splitting all combinations into

	<p><i>splits</i> parts and tune the <i>part</i>-th part (for Cruise).</p> <p>If <code>key_stats_only = True</code> then don't calculate non important stats</p> <p>Parameters: <code>key_stats_only</code> – bool</p>
<code>read_in_tuning_result_df(address)</code>	<p>Read in existing DataFrame from .csv consisting of tuning result.</p> <p>Automatically populates result array and checked array if csv columns match parameter choices</p> <p>Parameters: <code>address</code> – str – include '.csv'</p>
<code>set_tuning_best_model_saving_address(address)</code>	<p>Set address for exporting best model as a pickle</p> <p>Parameters: <code>address</code> – str – does not need to include '.pickle'</p>
<code>view_best_combo_and_score()</code>	<p>View the current best combination and its validation score</p>

Objects:

<u>Objects</u>	<u>Purpose</u>
train_x	DataFrame
train_y	Series
val_x	DataFrame
val_y	Series
test_x	DataFrame
test_y	Series
tuning_result	DataFrame
model	model class
parameter_choices	Dictionary -str:list – str is hyperparameter name (strictly as defined in model class), and list is sorted values of hyperparameter which we want to try out.
hyperparameters	list
feature_n_ningxiang_score_dict	Dictionary -str:float – str is hyperparameter name (strictly as defined in model class), and float is its NingXiang score
non_tuneable_parameter_choices	Dictionary -str:str/float/int - str is hyperparameter name (strictly as defined in model class), and values are valid hyperparameter values for model
checked	np.array
result	np.array
checked_core	np.array

	<p>value = 1: appended onto list of cores to be checked</p> <p>value = 2: actually checked as a core</p>
been_cruised	<p>np.array</p> <p>value = 1: been checked as core, so don't need to be appended as a cruise</p> <p>value = 2: actually checked as a cruise combo</p>

Test Result (Corr)

1. Time

YangZhou's algorithm will undoubtedly take more time than JiXi on top of the required time for tuning; but from testing, the maximum time required to run YangZhou on a dataset modelled on real data was 13.5435 seconds on Google Colab, which is approximately the time to train one combination for the average model.

Thus, YangZhou should be a time saver considering the amount of hyperparameter combinations it doesn't need to tune, especially if each hyperparameter combination takes a long time to tune.

2. Accuracy

<u>Batch</u> (Corr)	<u>Percentage of test cases</u> <u>when Algorithm output ==</u> <u>Actual Max</u>	<u>Percentage of test cases</u> <u>Algorithm output >=</u> <u>Actual Max – 0.005</u>
1	97.39%	99.96%
2	94.00%	99.63%
3	95.00%	100.00%
7	93.33%	100.00%

<u>Batch</u>	<u>Algorithm output ==</u> <u>Actual Max</u>	<u>Algorithm output >=</u> <u>Actual Max – 0.005</u>
Real (4)	95.65%	100.00%

The maximum difference between algorithm output and actual max in batch 4 (real data) was 0.0007.

3. Percentage of Hyperparameter Combinations searched

<u>Batch</u> (Corr)	<u>Mean</u>	<u>Median</u>	<u>Max</u>
1	23.57%	18.34%	88%

2	17.27%	13.17%	71.43%
3	12.12%	6.21%	71.43%
7	14.31%	7.29%	76.67%

<u>Batch</u>	<u>Mean</u>	<u>Median</u>	<u>Max</u>
Real (4)	56.16%	56.81%	74.3%

On average, YangZhou only tunes less than 60% of all designated hyperparameter combinations.

Test Result (Interact)

1. Time

YangZhou's algorithm will undoubtedly take more time than JiXi on top of the required time for tuning; but from testing, the maximum time required to run YangZhou on a dataset modelled on real data was 13.5435 seconds on Google Colab, which is approximately the time to train one combination for the average model.

Thus, YangZhou should be a time saver considering the amount of hyperparameter combinations it doesn't need to tune, especially if each hyperparameter combination takes a long time to tune.

2. Accuracy

<u>Batch</u> (Interact)	<u>Percentage of test cases</u> <u>when Algorithm output ==</u> <u>Actual Max</u>	<u>Percentage of test cases</u> <u>Algorithm output >=</u> <u>Actual Max – 0.005</u>
1	97.92%	99.65%
2	93.33%	97.5%

<u>Batch</u>	<u>Algorithm output ==</u> <u>Actual Max</u>	<u>Algorithm output >=</u> <u>Actual Max – 0.005</u>
Real (3)	95.65%	100.00%

The maximum difference between algorithm output and actual max in batch 3 (real data) was 0.0007.

3. Percentage of Hyperparameter Combinations searched

<u>Batch</u> (Interact)	<u>Mean</u>	<u>Median</u>	<u>Max</u>
1	31.64%	29.39%	92%
2	18.79%	13.03%	64%

<u>Batch</u>	<u>Mean</u>	<u>Median</u>	<u>Max</u>
Real (3)	56.16%	56.81%	74.3%

On average, YangZhou only tunes less than 60% of all designated hyperparameter combinations.
